

Fucoidan-dependent Increased Membrane Components in HepG2 Cells: Effect of Fucoidan Is Not Due to Gene Expression

KOU HAYAKAWA¹ and TAKEAKI NAGAMINE²

Abstract. *Background: The precise mechanism of the therapeutic effects of fucoidan (sulphated polyfucose) on cultured hepatocarcinoma HepG2 cells is as yet unclear. Materials and Methods: Protein components between fucoidan-treated and non-treated HepG2 cells were compared through a quantitative micro-sequencing method. Results: A dramatic and immediate increment of the membrane compartment and a decrement of RNA virus by fucoidan, as an effect of the Ishi-Mozuku (an edible brown seaweed Mozuku of Japan), are demonstrated. The ratio of membrane glycoproteins to total cellular proteins increases from 28.9% to 43.2% (1.5-fold), and the positive-sense single-stranded RNA viral proteins among the total cellular proteins decrease from 5.3% to 0.29% (18-fold), respectively, in response to 0.102 mg/ml fucoidan in HepG2 cells over three days' period. Conclusion: Fucoidan seems to retard the growth of HepG2 cells through membrane glycoprotein metabolism. Therefore, fucoidan could be expected to have a therapeutic effect on hepatocellular carcinoma.*

Dedication: In memory of the encouragement of my beloved daughter Reiko Hayakawa (21 November 1979 – 1 February 2007).

Key Words: Direct micro-sequencing, proteomics, protein determination, invaded microbes, membrane protein, hydrophobicity, de-anchoring, liver cancer, HCC, HCV, HIV, viral proteins, Ishi-Mozuku, fucoidan.

Our research group has previously shown that covalent binding of the proteins to glass-fiber disk is very important for quantitative direct-microsequencing (1).

Direct-microsequencing using 1-ethyl-3-(3-dimethyl-aminopropyl)-carbodiimide (EDC) (2) has been successfully applied to protein component analysis in the human bile and human pancreatic juice (3).

Thus, we have applied this method to analyze homogenates of liver tissues, and of liver cell lines. It has been found that cultured hepatoblastoma cells (HuH-6) and retinoblastoma cells (Y79) mainly contain histone H3.1 in their homogenates, but tissues of adult livers mainly contain haemoglobin A (HbA) and albumin (4). Immortalised cultured cell lines seem to produce augmented histone H3.1 (4), and also D-aspartic acid (5). Furthermore, HCC tissues of the livers of LEW rat show a 10-fold increase in free-form biotin, compared to corresponding LC tissues (6).

Furthermore, these lines of evidence have been clearly re-confirmed by separating the homogenate sample into the supernatant and membrane fractions by ultra-centrifugation (100,000 × g, 90 min, 4°C). In the present article, we extend and apply the improved direct-microsequencing deciphering method on fetal liver cells of Hc and on hepato-carcinoma HepG2 cells. It has been confirmed that Hc cells also contain high amounts of histone H3.1 (5.5% (w/w) among the total cellular proteins). The high content of histone H3.1 in the HepG2 cells is not changed by fucoidan treatment. We report on changes in the metabolism of membrane glyco-proteins of HepG2 cells in response to added fucoidan in the culture medium at 0.102 mg/ml. We also discuss on the mechanism of retardation of growth of HepG2 cells by fucoidan.

Materials and Methods

Chemicals and reagents. Standard PTH-amino acids (20 amino acids were mixed), 1-ethyl-3-(3-dimethyl-aminopropyl)-carbo-diimide (EDC), pyridine (biochemical grade), 4-vinylpyridine, tri-n-butylphosphine, acetone, chloroform, methanol, dimethylformamide (DMF), and trifluoroacetic acid (TFA) treated glass fiber disk were obtained from Wako (Osaka, Japan). Bovine serum albumin (BSA),

Figure 1. Typical linear yield-line of PTH-amino acid obtained from the purified β -lactamase TEM fragment (analyzed from 24th to 76th amino acid residues of mature chain) of *Escherichia coli* O-157. A direct binding method with EDC was used. Hydrophobicity of this β -lactamase TEM fragment was considered to be relatively high (0.552), and this fragment was considered to be the membrane protein. Correction by the yield of PTH-amino acid was performed using Table I.

non-edible fucoidan (from brown seaweed Mozuku (*Fucus vesiculosus*) of Ireland), and diethylnitrosamine (DEN) were purchased from Sigma (St. Louis, MO, USA). 3-Aminopropyltriethoxy-silane was from Shin-Etsu Chemical, Tokyo, Japan. Fetal calf serum (FCS) was from Moredgate BioTech (Blimba, Australia). Chromatographically purified β -lactamase TEM fragment (from 24- of mature chain) of *Escherichia coli* O-157 was kindly provided by Dr. Manabu Tagawa (Department of Gastroenterology, National Research Institute for Child Health and Development; Now The Takeda General Hospital, Aizu-wakamatsu-city, Fukushima, Japan) (Figure 1). The hepatoblastoma cell (HuH-6; from pediatric hepatoblastoma, 1-year-old Japanese male baby), the Japanese hepatoma cell (HuH-7; from HCC liver of 57-years-old male), and the American hepatoma cell (HepG2; from HCC liver of 15-years-old black male) were kindly provided by Rikagaku Kenkyusho (Tsukuba, Japan). Normal human fetal-hepatocyte cells (Hc) were kindly provided by Graduate School of Health Sciences, Gunma University (Maebashi, Japan).

Human liver autopsy and biopsy samples (HCC and corresponding non-tumorous tissues) were obtained from the Gunma University Hospital and the Nishi-Gunma Hospital as previously described (6). Informed consent was obtained from all patients and/or their relatives. This study was approved from the institutional committee for the study of human rights. Male LEW rats were purchased from Sankyo Labo Service Co., Tokyo, Japan, and tested for HCC as described previously (6). All the protocols for tests in rat were carried out in accordance with ethical guidelines for laboratory animals of National Research Institute for Child Health and Development.

Brown seaweeds of Ishi-Mozuku (*Sphaerotrichia divaricata*) and Kinu-Mozuku (Silky-Mozuku; *Nemacystis decipiens*) were purchased from Koh-Sushi Co., Anamizu-cho, Ishikawa, Japan. Edible fucoidans were extracted with acetic acid-water 1 : 2 (v/v), purified by 80% ethanol-aggregation method, and dried by us from these edible brown seaweeds Mozukus. Okinawa-fucoidan was prepared from the brown

seaweed Okinawa-Mozuku (Futo-Mozuku; *Cladosiphon okamuraus*) as previously described (7). This Okinawa-fucoidan (containing glucose) surely inhibited the biotinidase activity (*Kip*) in the cell-free homogenates of liver HCC tissues. However, it turned out that this glycan did not inhibit the growth of the adults' HuH-7 and HepG2 cells at all, but inhibited the growth of the baby's HuH-6 cells. Therefore, this fucose-polymer glycan (containing glucose) was re-named as "Okinawa-fucoidan" in this text, since chemical structures seemed to be different from the fucoidan (pure sulphated poly-fucose).

Cell culture and preparation. Cell cultures were performed on usual non-coated plastic plates for HuH-7, and other cells were cultured on collagen-coated plates. Fucoidan from Ishi-Mozuku (*Sphaerotrichia divaricata*) was used at 0.102 mg/mL. Cells were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum (FCS), streptomycin (100 U/mL) and kanamycin (100 U/mL) in a humidified 37°C/5% CO₂ incubator. In order to compare suitably or reproducibly, cells were harvested after 3-days of culture (late-log-phase) with cell scraper (Corning), and obtained cells washed three-times with phosphate buffered saline (PBS) and cell volume was measured. Our previous work indicated that the gene expression was very sensitive to environmental nutrition and cell division cycle or growth phase (8), therefore we decided to compare as simple as possible in order to elucidate the differences occurred between normal and cancer state. Thus, elucidation was performed by the comparison of different specimens as far as we could. Washed cells were stored in liquid nitrogen at -196°C until use.

Direct-microsequencing. Homogenates of HepG2 and other liver cell lines were prepared as previously described (4), and were ultracentrifuged at 100,000 $\times g$ for 90 min at 4°C (Beckman L8-M Ultracentrifuge; Rotor Type 35). Obtained membrane fraction and

Table I. Calculation method for each PTH-amino acid derived from the PPSQ-21A protein sequencer (Shimadzu)*.

PTH-amino acid	True amount of amino acid in proteins (pmol) Factor
Asp (D)	measured (pmol) × 8.7
Glu (E)	measured (pmol) × 6.0
Asn (N)**	measured (pmol) × 7.8
Gln (Q)**	measured (pmol) × 4.6
Ser (S)	measured (pmol) × 20.7
Thr (T)**	measured (pmol) × 10.9
His (H)	measured (pmol) × 6.1
Gly (G)	measured (pmol) × 5.1
Ala (A)	measured (pmol) × 3.4
Tyr (Y)	measured (pmol) × 3.7
Arg (R)	measured (pmol) × 8.5
Cys (C)	measured (pmol) × 11.0
Met (M)	measured (pmol) × 6.2
Val (V)	measured (pmol) × 6.0
Pro (P)	measured (pmol) × 5.1
Trp (W)	measured (pmol) × 4.3
Phe (F)	measured (pmol) × 3.7
Lys (K)	measured (pmol) × 4.0
Ile (I)	measured (pmol) × 2.8
Leu (L)	measured (pmol) × 3.6

*pmols PTH-amino acid are calculated at attenuation 3. **15% of Asn (N) becomes to Asp (D), and 9% of Gln (Q) to Glu (E). If Gln or Asn is a major amino acid component, correction is performed. 50% of PTH-Thr becomes to PTH-ΔT (5-ethylidene-3-phenyl-2-thio-hydantoin).

supernatant fraction were stored in aliquots at -196°C until use. Protein determinations of membrane- and supernatant-fractions were performed by our SEC-HPLC protein determination method (3, 4, 10, 11).

Direct-microsequencing was performed three-times by using both of these supernatant- and membrane-fractions (0.08 mg of protein) as described previously (4) by using a PPSQ-21A protein sequencer (Shimadzu, Kyoto, Japan). Proteins are bound covalently to the glass filters with EDC according to the method of Salnikow *et al.* (2), and cysteine as PEC is measured automatically (9). Reproducibility of production of PTH-amino acids is essential, and soluble cellular and membrane samples, which were stored at -196°C, are found to be important for high binding-rate. If fresh sample is used, the amount of total identified proteins usually becomes 100±10% the amount of proteins, as determined independently by our SEC-HPLC protein-determination method. Reproducibility of this method depends only on the appeared PTH-amino acids, and direct-microsequencing is repeated three times. Then, the mean values are used for the next deciphering algorithm (this algorithm requires usually two weeks for the supernatant sample, and further two weeks for the membrane sample manually). Thus, a computer-aided software program of this deciphering algorithm is expected to be devised in order to obtain the analytical result promptly.

Determination of liberated PTH-amino acids is performed with the correction factors as shown in Table I. These correction factors are unique to the individual Shimadzu PPSQ-21A protein sequencer. Trial to increase of the yield (or factors) of Ser and Thr by using HCl instead of TFA is not yet possible, since production of NaCl

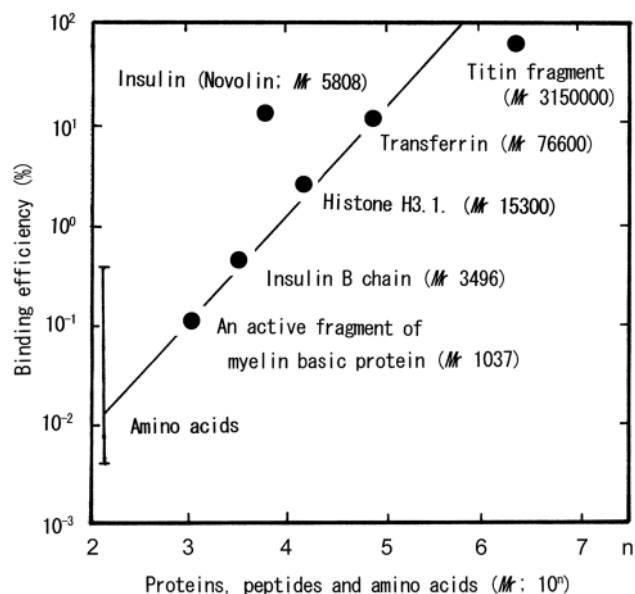

Figure 2. Dependence of binding efficiency in the EDC-binding method upon the relative molecular mass. Binding efficiency of representative protein was expressed in %. A linear correlation line was shown as in the log-log plot.

sometimes deteriorates the sequencer machine. If another protein sequencer is used, the correction Table I may again be changed.

Binding efficiency of various standard proteins by EDC is estimated, and is found to be dependent on the logarithm of the MW of proteins and peptides (Figure 2). Therefore, we used the correction factors in the protein determination process, using Figure 2, as follows; factor 1 for MW larger than 250,000, factor 2 for MW 40,000-250,000, factor 10 for MW 15,000-40,000, factor 50 for MW 5,000-15,000, factor 200 for MW 1,500-5,000, factor 714 for MW less than 1,500, respectively. If comparison of two samples of protein expression is necessary, standardization is performed.

Increase of PTH-amino acid (pmol of amino acids) of nth cycle is obtained by comparing to the previous (n-1)th cycle, these increments were scored. The amount of liberated amino acids from 1st to 20th cycle are usually determined and scored on a paper. Then, corrected estimations for the successive amino acid sequence (*e.g.* A-A-A-A or D-D-D-D *etc.*) are performed by comparing amount of pmol at (n+2) th, (n+1) th, n th, and (n-1) th cycles for each amino acid; *i.e.*, when most high values are observed at the (n+2) th and the (n-1) th cycle, the second high value is displaced into the (n+1) th and the n th cycles.

Deciphering algorithm method. Firstly hemoglobin-alpha and -beta (HbA) were calculated in the case of human serum and tissue or rat tissue samples, and subtracted from the scored table. Since cultured cells except for fetal liver cells (Hc) did not contain HbA, this step was omitted. Then, in the case of liver tissues and liver cell lines, ceruloplasmin [precursor (1-), mature (19-), and fragment (214-)] and transferrin [precursor (1-), mature (19-)] were calculated and subtracted. The reason why the fragment of ceruloplasmin (from

*Viral, bacterial and plant proteins are present at 18.6%. The amount of viral proteins in Hc cells (4.7%) is similar to HepG2 cells (6.6%). Traffic accident might have introduced the proteins (or genes) of plant proteins (indicated in bold letter). Viral proteins are indicated in red. Membrane proteins are indicated in italics. Cysteine residues at 1972 and 1976 of genome polyprotein (HCV) are S-palmitoylated. Cysteine residue at 771 of envelope glycoprotein gp160 (HIV-2) is only S-palmitoylated at one site, hydrophobicity is 0.54, and it may come from the soluble fraction. # ds RNA virus. ### ds DNA virus. * +ss RNA virus.

214-) is always detected was not yet fully-understood at this time. Then, albumin, albumin-precursor, alpha-fetoprotein (AFP) and AFP-precursor were calculated and subtracted. The major protein of rat skeletal muscle is unexpectedly found to be rat albumin, therefore it should be subtracted in this case. In the case of cultured cells, biotin synthetase of bacterial sequences (*Bacillus subtilis* or *Helicobacter pylori*), and lipoic acid synthetase of *Bacillus subtilis*'s or human sequence were detected, and calculated to subtract. Then, sequences of our human serum biotinidase (DQPGEVAVADVAQVY-) (12) and human urine (or kidney) biotinidase (our unpublished result; *i.e.*, AVPPQVGNQEGQTN-) were calculated and subtracted. In the case of the N-terminal portion of the human serum biotinidase, two or three amino acids were observable at the same position; *i.e.*, in 1st(A, K, S), 2nd (N, H), 3rd (D, N), 5th(D), 6th(P), 12th (E, F), 13th (F, L), 14th (A) of amino acid residues (12). In these cases, amount of amino acids was divided according to the amount of amino acid present, and subtracted from these amino acids in the table. The sequence of milk-type biotinidase (our unpublished result; FPSYVAVTKV VPPYG-) was not detected in the serum, but appeared in the fetal liver cells (Hc cells). The sequence of human serum biotinidase reportedly by Cole *et al.* (13) (AHTGEESVADHHEAE-) only appeared in the fetal liver cells (Hc cells) and the serum of the inflammatory patients. Therefore, this sequence as reported by Cole *et al.* may be re-named as the fetal-biotinidase or the inflammatory-biotinidase. However, the following database searches could not be continued at all without using these

biotinidase sequences, since biotinidase was one of major component proteins in the liver and serum in humans.

Then, the remaining amino acid amounts were scored again in table format. The major amino acid sequence of 14 digits from the table (from 3rd to 16th) was then searched for by using the protein database tool of Protein BLAST (Basic Local Alignment Search Tool) of NCBI (National Center for Biotechnology Information) at the URL http://blast.ncbi.nlm.nih.gov/Blast.cgi?PROGRAM=blastp&BLAST_PROGRAMS=blastp&PAGE_TYPE=BlastSearch&SHOW_DEFAULTS=on&LINK_LOC=blasthome

If several high-score amino acids were present at the same position, a random search was performed in the case of two amino acids. If more than two amino acids were present, then redundant sequences of same amino acids were tested. Proteins showing more than 6 matched digits were chosen, and were included on the other table. After referring the database, sequences were extended to indicate 1st to 16th digits. Usually a higher than 90% protein matching was considered to be highly possible to be present in the sample, and the mol amount of the protein or protein fragment was calculated. If the database search was suddenly stopped, search on viral and bacterial proteins was subsequently performed. Since antibiotics against bacteria were present in the culture medium, established cultured cells usually contained no invaded bacterial proteins. Then, matching to a viral protein usually occurred, and this viral protein was chosen. The appeared amount (pmol) of matched amino acid were then plotted on the semi-logarithmic graph sheet,

*Amino acid sequence of the putative human fetal-biotin-synthetase has not yet been available. Sequences of human milk biotinidase milk biotinidase was isolated from a mixture of human milks provided by several lactating females and fetal/inflammatory biotinidase (NCBI, PubMed; UniProtKB/Swiss-Prot: P43251.2) were FPSYVAVTKVVPPYG- (1st V, 7th N, and 11th I was also detected as assessed by direct-microsequencing) and AHTGEESVADHHEAE-, respectively. Proteins coming to the membrane fractions are indicated in italics.

molecular mass (MW) of protein or fragment of protein matching was calculated, and corrected by the binding factor according to the MW. Then, we created a table in a work sheet of Microsoft Excel. If 8 digits of search were not possible to continue, this step was the termination point in the direct-microsequencing-deciphering algorithm search. Usually, 40-times of sequence searches of 8 digits were performed, and about 120 proteins and/or protein fragments were identified in the supernatant or membrane fraction of livers and cultured liver cell lines. About 70% of proteins were N-terminal

closed in eukaryotic cells (14), but only 5% (Q among 20 amino acids) might be strongly closed by pyroglutamic acid. Therefore, each supernatant- or membrane-fraction seemed to contain approximately 125 proteins; $120/(1-0.05)=126$ species of protein molecules. Thus, approximately 250 species of proteins seemed to be present in the human livers and cultured liver cell lines.

Protein hydrophobicity. Hydrophobicity of the proteins is defined as; Hydrophobicity=1 – Hydrophilicity. Hydrophilicity was defined as

Table V. Viral proteins of HepG2 cells without addition of fucoidan.1

Proteins of retrovirus are indicated as red letters, HCV and HGV proteins are in blue. RNA viruses are present at 83.3% among viruses. Retroviruses are present at 23.3% among viruses, and HCV and HGV at 32.1%. Membrane proteins were indicated in italics. Cysteine residues at 769 and 842 of envelope glycoprotein gp160 (HIV-1) are S-palmitoylated. 79% ($1.7/(1.7+5.7+0.8)=0.79$) of the envelope glycoprotein gp160 (HIV-1) is deanchored state. Cysteine residues at 1972 and 1976 of genome polyprotein (HCV) are S-palmitoylated, but this protein fragment in this table (821-) is hydrophobic (0.586) and is sufficient to be present at the membrane fraction. Cysteine residues at 569 and 572 of envelope glycoprotein gp95 (Rous sarcoma virus) are S-palmitoylated, but this protein fragment in this table (462-) is hydrophobic (0.604) and is sufficient to be present at the membrane fraction. # ds RNA virus. ## ds DNA virus. * + ssRNA virus. ** -ss RNA virus.

follows: (Asx + Thr + Ser + Glx + Lys + His + Arg)/(total amino acid) (15). Hydrophobicity larger than the value of 0.55 is tentatively considered to be the hydrophobic membrane protein in this text, since this hydrophobicity value of Reference 15 is well-coincided to the definition of the membrane protein as determined by the ultracentrifugation method; *i.e.*, membranes were defined as the cellular components precipitated at $100,000 \times g$ for 90 min at 4°C.

Determination of lipoic acid (thioctic acid; lipoate). The amount of total lipoic acid (thioctic acid) in rat livers were determined by a newly-developed high-performance affinity liquid chromatography (16).

Statistics. Since the numbers of the data to be compared were insufficient for estimating the distribution pattern, non-parametric

analysis was applied in this text. Therefore, values are indicated as the median and range. Non-parametric statistical analysis was performed according to Reference 17.

Results and Discussion

We first constructed a correction table to estimate the amount of amino acids present in the protein sample from the provided PTH-amino acid (pmol) reading of the machine (Table I). Degradation of Ser and Thr during microsequencing was indeed large as expected by the use of TFA (Table I), however such a good yield line was obtainable following correction factors in Table I, using purified

¹Proteins of retrovirus are indicated as red letters, and HCV and HGV were in blue. Fucoidan from Ishi-Modzuku was added at 0.102 mg (dry weight)/mL DMEM medium for 3 days. Retroviral proteins are dramatically reduced from 23.3% to 2.0% (11.7-fold) among viral proteins by the treatment with fucoidan for 3 days. RNA viruses are present at 15.0 % among viruses. Membrane proteins are indicated in italics. Cysteine residues at 1972 and 1976 of genome polyprotein (HCV) are S-palmitoylated, but this protein fragment in this table (RNA-directed RNA polymerase portion; RdRp) may not contain palmitic acid, but hydrophobicity (0.565) of this fragment is sufficient to be present at the membrane fraction. # ds RNA virus. ## ds DNA virus. * +ss RNA virus. **-ss RNA virus.

β-lactamase TEM fragment (from 24- of mature chain) of *Escherichia coli O-157* (Figure 1). The binding efficiency of proteins by the EDC method was logarithmically-depended upon the MW of the proteins and peptides as shown in Figure 2. Therefore, we corrected the protein amount by using this log-log line of Figure 2 (correction factors are shown in the Materials and Methods section).

The component proteins of Hc cells (fetal liver cultured cells) were determined, and are presented in Table II (viral and bacterial proteins) and Tables III and IV (cellular proteins).

The component proteins of HepG2 (derived from an HCC liver of 15-year-old male from the USA) were also determined and are summarized in Tables V and VI (viral proteins with and without treatment of fucoidan), Tables VII-IX (cellular proteins; without treatment of fucoidan) and Tables X-XIII (cellular proteins; with treatment of fucoidan for 3 days).

Fetal cultured Hc liver cells contained 19% of the invaded microbes (virus, bacteria, and plant) (Table II), which was of

similar level to human breast milk (16%; virus, bacteria, and yeast) and to cow's milk (17%; virus, bacteria, and yeast) (data not shown). Interestingly, bacteria of *Lactobacillus casei* (*Shirota*) contained 12% of invaded bacteriophages (data not shown). Human biopsy tissues of hospitalized patients also showed similar results, but major virus and minor bacteria were detected; *i.e.*, pseudo-cancer of liver (non-cancer) contained 19%, the LC portion of the leprosy patient 15%, HCC portion of primary biliary cirrhosis (PBC) patient 30%, respectively, of the invaded microbes (virus and bacteria) among total tissue proteins (data not shown). It is also interesting that the DNAJ protein (Hsp40; Heat shock protein 40 kDa of *Mycobacterium leprae*) appeared only in the LC portion of the leprosy patient, which suggested that the sensitivity of detection power of proteomics was highly and sufficiently performed by this microsequencing method. The liver of the leprosy patient also contained the unique soil-related plant-tumor making bacterium *Agrobacterium*

tumefaciens, and plant virus (*Yellow mosaic virus*) proteins, suggesting that co-infection of *Mycobacterium leprae*, *Agrobacterium tumefaciens*, and plant virus (*Yellow mosaic virus*) in the patient might have occurred. Increased histone H3.1 in the LC portion of the liver of the leprosy patient has been also detected. High levels of total histone H3 transcripts (mRNA) in different tissues of plant *Alfalfa* has been reported showing a particularly high level in the somatic embryos (18). Thus, histone may be essential for immortality in plant cells and in human leprosy cells, but seemed not to be directly related to human cancer. Furthermore, the liver biopsy of HCC patient with *HCV* contained only viral proteins (LC tissue 12% and HCC tissue 16%, respectively, among the total tissue proteins), suggesting that antibiotics against the bacteria might have been used during hospitalisation of the patient. Fetal Hc liver cells contained 19% of invaded microbes; *i.e.*, 4.7% viral and 14% bacterial proteins (Table II). Since fetal Hc cells were prepared from the mixed fetal-livers obtained from the pregnant women who died of traffic accidents in USA, immediate infection by the invading microbes (virus, bacteria, and plant) might have occurred. These invaded microbes might still persistently have been remained in cultured Hc cells (few times of the passages of culture) in spite of the presence of antibiotics against bacteria in the culture medium. On the other hand, established hepatocarcinoma HepG2 cells were cultured for numerous passages with antibiotics, and bacterial proteins fully disappeared (Table V). Thus, the content of viral proteins in Hc cells (4.7%; Table II) and in HepG2 cells (4.6%, Table VI, cultured with fucoidan) finally returned similar values. However, the viral content of HepG2 cells without fucoidan treatment was considerably higher (6.6%, Table V). The median viral content in the serum of non-cancer persons was 3.1% (n=9; range 0.4-4.5%) (19). Biopsies of livers of three HCC patients and a pseudo-cancer patient contained very high virus content, of 13.5% (n=5; range 8.1-22.2%), although the data of the virus content in the non-cancer and non-inflammatory healthy livers were not obtainable. Therefore, the metastasis of cancer might easily occur by infection or diffusion of virus to other organs (20). Viral protein content in washed cells and serum, higher than 5% among the total cellular proteins might be an indicator for "the state of cancer". However, prompt determination of viral content may be difficult using the microsequencing method, which requires for analysis time of about one month using the presently used manual microsequencing algorithm.

HCV genome polyprotein is an anchored membrane glycoprotein (21, 22), and is detectable in the membrane fractions of cultured cells of Hc and HepG2, and of livers of diseases (n=4). Non-cancer fetal Hc cells contain 7.7 µg (0.77%; MW 250,000) HCV genome polyprotein (Table II), which may not be deanchored. Its level in hepatocarcinoma HepG2 cells is 7.2 µg/mg (0.72%; MW 250,000; Table V), but

this may be deanchored. Fucoidan seems to reduce it to 2.0 µg/mg (0.20%; MW 83,000; Table VI), and the protein may not be of the deanchored state. The presence of HCV genome polyprotein in the liver tissues is also observed; *i.e.*, pseudo-liver-cancer 0.44% (membrane MW 130,000), LC tissue of leprosy 2.2% (membrane; MW 230,000), HCC tissue of PBC 3.5% (soluble; MW 230,000), LC tissue of a HCC with HCV 0.79% (soluble; MW 40,000) and HCC tissue of a HCC with *HCV* 0.55% (membrane; MW 340,000), respectively (data not shown). MW of HCV genome polyprotein in the non-cancer state tissues and the fucoidan-treated HepG2 cells seems smaller compared to the cancer state. Therefore, the presence of a large molecular mass HCV genome polyprotein in liver cells may be a risk factor for HCC or liver cancer with immortality.

Envelope glycoprotein gp160 (HIV) was dramatically reduced by fucoidan in HepG2; *i.e.*, from 8.2 µg/mg (0.82%; without fucoidan) to 0.0 µg/mg (0.0%; with fucoidan) (Tables V and VI). Although data in other hepatocarcinoma cells such as HuH-7 may also be necessary to derive a conclusion, fucoidan may be important for cancer cells to obtain the normal innate immune system by reducing HIV virus. Only a minor amount of the membrane protein Nef of HIV remained at the same levels (Table V; without fucoidan 0.6 µg/mg, and Table VI; with fucoidan 0.9 µg/mg) by fucoidan, however the HIV-1 Nef-interacting protein (T-complex protein 1 subunit eta; membrane protein made from the cellular DNA gene) is expressed in the fucoidan-treated HepG2 cells (Table X; 4.2 µg/mg). Therefore, the virulent viral Nef protein remaining in fucoidan-treated HepG2 cells may be neutralized by this cellular membrane protein (23). Fucoidan made from the edible *Ishi-Mozuku* at 0.102 mg/mL, dramatically reduces the proteins of plus-sense (+) single-stranded (ss) RNA virus from 5.3% to 0.29% (18.1-fold reduction) among the total cell-proteins (Table V and Table VI), while proteins in Hc cells are 3.6% (Table II). Hepatitis virus (*HCV* and *HGV*) plus retrovirus (*HIV* and *Rous Sarcoma virus*) are also reduced from 3.7% to 0.29% (12.6-fold reduction) among the total cell proteins (Tables V and VI), and those in the Hc cells is 1.1% (Table II). Reduction of retrovirus of *HIV* and *Rous Sarcoma virus* is also reduced from 2.3% to 0.2% (11.7-fold reduction) among the total cell proteins (Tables V and VI), and those in the Hc cells is 0.34% (Table II). HIV is a notorious virus responsible for human immunodeficiency (AIDS), and reduction of retroviral proteins seems to be essential for cure of HCC (24). Human papillomavirus (*HPV*) infection appears to be a necessary factor in the development of almost all cases of cervical cancer (25). Tumor formation in plants by the bacterium *Agrobacterium tumefaciens* has turned out to be caused by a symbiotic tumour-inducing (*Ti*) plasmid (or phage virus) (26). *Helicobacter pylori* infections have been linked to gastric adenocarcinoma (27), and the

*Proteins of the membrane fractions are indicated in Italics. Titin is a serum marker of adulthood; *i.e.* titin is detectable in HepG2 (from male HCC liver of 15 years of age) but not detected in Hc (from fetal livers).

transformation of the gastric cancer cells may be speculated to have occurred by the plasmid or virus residing in this bacterium such as in the case of the tumour-inducing (Ti) plasmid residing in the plant bacterium *Agrobacterium tumefaciens* (26). Furthermore, virus or phage infection changes the surface glycochains of the dominated host cells (phage conversion), and prevents the invasion of other virus or phage to enter the conquered cell. Thus, glycochains of the cell surface may be changed by the invaded viral glycochain-converting enzymes (28). Therefore, the virus infection to the host cells may be an important issue for cancer and metastasis, and this glycochain conversion may be performed by the viral enzymes and viral genes but not by the cellular enzymes or cellular genes; *i.e.*, cellular gene expression may not be directly related to cancer differentiation. Fucoidan may directly prevent the infection from virus, and the possibility of direct inhibition of HIV reverse transcriptase activity by fucoidan *in vitro* has already been reported (29). Other DNA viral proteins seem to increase within the three days of fucoidan treatment; 11.0 $\mu\text{g}/\text{mg}$ (without fucoidan) to 38.4 $\mu\text{g}/\text{mg}$ (with fucoidan) (Tables V and VI). However, this level of DNA virus might also be reduced during the longer treatment time by fucoidan due to the slow-preventing effect against DNA virus; *i.e.*, oral administration of fucoidan for 3 weeks had been necessary in the mice cases (30). Following, fucoidan seems to dramatically reduce the viral proteins through direct inhibition of viral replication; *i.e.*, immediate inhibitions on viral protein synthesis and viral genome replication.

Comparative biochemical studies among normal liver tissues and cultured cell lines (human Hc, HuH-6, HuH-7, HepG2, rat RLC-16, and retinoblastoma cells (Y79)) indicated that the following characteristics were the unique points of the immortal cell lines; *i.e.*, [1] increase of +ssRNA virus, [2] occurrence of biotin production (adult humans

could not synthesize biotin) (vitamin H) (6, 31, 32), [3] increase of biotinidase activity (Kip; repulsion power against produced biotin) (6), [4] appearance of D-aspartic acid (though the HepG2 showed a relatively low concentration) (5), [5] decreased ratio of membrane proteins (in the follows of this text), [6] increased production of histone H3.1 (3, 4). High concentration of biotin (both the total- and free-form) (32, 33) and high biotinidase activity (unpublished observation) was found in the chicken egg yolk. Interestingly, fucoidan seemed not to influence cellular gene expression in HepG2 at all; *i.e.*, histone content of non-treated and treated with fucoidan HepG2 cells were unexpectedly similar.

Apoptotic mechanism by Wakame-fucoidan (containing 11% of uronic acid) from "Wakame" (*Undaria pinnatifida*) has been recently reported by using the human HCC cell line SMMC-7721 (the Cell Bank of the Chinese Academy of Sciences, Beijing, China) (34), however stopping of cell division at the S-phase (DNA-replication phase) by fucoidan is not significant. Furthermore, apoptosis-related proteins such as caspases and the gene products of *Livin* (a member of the inhibitors of apoptosis protein family) and XIAP could not be detected in HepG2 and Hc, and liver biopsies using the DMD method. The increased biotinidase Kip in the HCC tissue was inhibited only by the sulfated glycochains of fucoidan and heparin with the exception of chondroitin sulfate (6), indicating that both the sulfation and component sugar of glycochain was important to inhibit the glycoprotein enzyme biotinidase. Fucoidan and heparin were also known to inhibit blood coagulation *via* binding to the glycochains of glycoprotein antithrombin III (35). Furthermore, anti-tumor and anti-metastatic activities of lung adenocarcinoma in mice exerted by the fucoidan from *Fucus evanescens* have already been reported (36). In this case, intra-peritoneal injection method of 10 mg/kg/day of

Table VIII. Proteins of HepG2 cells without addition of fucoidan*.

*Proteins coming from membrane fractions were indicated in italics. Glycochain-synthesizing enzyme is indicated in bold.

fucoidan were used (36). Therefore, fucoidan may inhibit the above mentioned characteristics from [1] to [5] in immortalized cancer cells possibly through glycol-chains; *i.e.* [3] decrease of Kip of glycoprotein enzyme of biotinidase, [1] decrease of viral glycoproteins, and [5] the increase of the membrane compartment rich in glycoproteins, although the putative human genes and information of glycochain for [4] aspartate racemase and for [2] biotin synthetase are not yet available in the protein database (Protein BLAST in NCBI).

Attempts of growth-retardation tests directly by decreasing the intracellular concentrations of D-biotin and D-aspartic acid have not yet been successful. Thus, avidin addition in

the culture medium was tested in order to reduce the intracellular biotin concentration, but the HeLa cells were not affected at all, since avidin-biotin complex (MW65,000) was actively taken-up by the cells (37). Since oral administration of the high-molecular-mass Okinawa-fucoidan attenuated DEN-induced liver fibrosis in Wistar rats (38), the liver cells seemed to be able to take-up the high-molecular-mass fucoidan (MW 200,000) *via* the gut. Furthermore, intra-peritoneal injection of the high-molecular-mass fucoidan attenuated lung cancer in *C57Bl/6* mice (36), and the lung cells also seemed to be able to take-up fucoidan from different regions of the body. Then, a direct supply of amounts of biotinidase to promptly growing fetus and baby was

Table IX. *Proteins of HepG2 cells without addition of fucoidan**.

*Proteins coming from membrane fractions are indicated in Italics.

suggested, since chicken egg yolk (unpublished observation) and human breast milk (39) contained relatively high biotinidase. Recently, the direct demonstration of dependence on biotin for the growth of the mutant bacterium *Mycobacterium tuberculosis* has been reported (40). Our testing of addition D-aspartic acid (10 mM) in the medium of RLC-16 (immortalised epithelial cell line established in Japan from the liver of *Rattus norvegicus*), which required L-glutamine (10 mM) in the medium, had also been unsuccessful (5); *i.e.*, extremely high concentrations of D-aspartic acid (product) might have inhibited the aspartate

racemase reaction. Then, reduction of intracellular biotin and D-aspartate might have been achievable by addition of mercury ion, which is a common inhibitor to biotin synthetase (41) and to aspartate racemase (42). Therefore,

Lipoamidase precursor (mLIP; CEL; BSSL; 1-)	5.8		

*Fucoidan from Ishi-Modzuku was added at 0.102 mg/mL weight/ml DMEM for 3 days. Proteins coming to the membrane fractions are indicated in Italics. Titin is a serum marker of adulthood; *i.e.* titin is detectable in HepG2 (from male HCC liver of 15 years old patient) but not detected in Hc (from fetal livers).

the growth of the HCC-derived cultured cells may be expected to be slowed-down by the edible fucoidan through the above suggested five signals.

Although data obtained from hepatocarcinoma, such as HuH-7 cells, might be necessary to draw the conclusion, fucoidan from edible Ishi-Mozuku also seemed to change the amounts of cellular proteins; *i.e.* (1) increase of ceruloplasmin (1.4-fold), transferrin (1.6-fold), glycol-chain synthesizing enzymes (2.2-fold) and membrane receptors (1.4-fold) (Tables VII to XIII), and (2) decreases

of non-liver proteins of albumin (3.3-fold; skeletal muscle), alpha-fetoprotein (AFP; 1.9-fold; fetal liver), myosin (1.4-fold; muscle), titin (1.2-fold; muscle), protocadherin (brain) 8.1-fold, hypoxia-inducible factor (brain) 3.5-fold, and lipoamidase (1.8-fold; brain) (Tables VII to XIII). Increases in ceruloplasmin and transferrin

*Fucoidan from Ishi-Modzuku was added at 0.102 mg dry-weight/ml DMEM medium for 3 days. Proteins coming from the membrane fractions are indicated in Italics. Glycochain-synthesizing enzymes were indicated in bold.

turned-out to be non-general; *i.e.*, a liver of pseudo-cancer showed similar ceruloplamin levels to HCC tissues, and LC tissue of a liver of an HCC patient showed a decreased transferrin amount compared to HCC tissue. Decrease of albumin and AFP might also not be general; *i.e.*, although one HCC patient showed a decrease of albumin in HCC using chromatographic analysis (4), but increased albumin in HCC tissue was observed in an HCC patient, and increased AFP in the LC tissue of the leprocy patient was also observed using the microsequencing method. Instead,

changes in the glycochain of AFP seemed more important; *i.e.*, the highly-enhanced fucosylation of AFP in patients with germ cell tumor has already been reported (43). Since protein analysis of the liver tissues had been performed under the still unimproved micro-sequencing method, changes in the minor proteins seem to be meaningless.

Table XII. Component proteins of HepG2 cells treated with fucoidan for 3 days*.

Proteins (Cellular proteins; 95.4%)	Amount (µg/mg of protein homogenate)	Proteins (Cellular proteins; 95.4%)	Amount (µg/mg of protein homogenate)

*Fucoidan from Ishi-Modzuku was added at 0.102 mg dry-weight/mL DMEM medium for 3 days. Proteins coming from the membrane fractions were indicated in Italics. Glycochain-synthesizing enzymes were indicated in bold.

Thus, only the ubiquitously-expressed protein of lipamidase, glycol-chain synthesizing enzymes, and membrane receptors might have certain meaning as described below. The above discussed results of changes in cellular protein amounts are in line with those of previous results using 2-dimensional electrophoresis analyses regarding sexual differentiation (8).

On the other hand, fucoidan seems not to change the amounts of biotinidase, histone, ankyrin, and membrane active-transport proteins at all (Tables VII-IX and X-XIII).

Membrane active-transport proteins are constitutively important proteins for cell viability through nutrition uptake (44) and against toxins (mercuric ion) (45). Histone is not detected in liver of pseudo-cancer as expected, but is highly

Table XIII. *Proteins of HepG2 cells treated with fucoidan for 3 days**.

*Fucoidan from Ishi-Modzuku was added at 0.102 mg dry-weight/mL DMEM medium for 3 days. Proteins of the membrane fractions are indicated in italics. Glycochain-synthesizing enzyme was indicated in bold.

biotinidase and membrane active-transport proteins seem to be essentially important for cell viability. Fucoidan does not influence gene expression of these essential proteins regarding viability of the cells; *i.e.*, fucoidan may not act on the cell death mechanism of the cancer cells such as apoptosis. Then, this is the reason why fucoidan is a safe drug without side-effects on normal cells and organs.

An increase of biotinidase activity (*Kip*; inhibition constant by the product biotin, and *Cap*) in HCC tissues has been recently found (6). However, the amount of biotinidase protein in HepG2 cells (from an HCC patient of 15 years) is not changed (from 16.4 to 14.9 µg/mg) by treatment with fucoidan (Tables VII-IX and X-XIII). Interestingly, the amount of serum biotinidase in the biotin-deficient patient is also not changed by administration of biotin (10 mg/day) (19). These findings suggest that biotinidase is the non-inducible (constitutively expressed) protein indispensable for growth and viability of adult humans.

The fetal liver biotinidase (Hc cells; 6.2 µg/mg) is firstly found at this time (Table IV), which suggests the important role of fetal biotinidase during fetal growth. Human serum biotinidase seems to be expressed in an age-dependent differentiation manner; *i.e.*, gradual increase of serum biotinidase to the adult level within 3 months after parturition, and the age-dependent gradual increase (highest activity; at 18.7 years of age), and decrease of the activity level to zero at the age of 174 years (47). Biotinidase is a known glycoprotein enzyme (48), and ubiquitous biotinidase activity in rat tissues are variable according to tissue

expressed (1.2%) in the LC tissue of leprosy patients. Histone may not be important for the cancer, but may be essential for the immortality of cells. Ankyrin (an S-palmitoylated anchored membrane protein) is also essential for cell viability through maintaining the cell morphology (46), but does not appear in the liver tissues except LC and HCC tissues of one HCC patient with *HCV*. Therefore,

differences; *i.e.*, tissue difference of biotinidase activity occurs not by difference in biotinidase gene but the different glycochain of biotinidase (12, 47, 48). Then, decrease of biotinidase activity together with decrease of biotin by fucoidan may be caused by a possible binding of fucoidan to the glycochains of biotinidase.

Membrane-glycoprotein-enzyme lipoamidase is rich in the pig brain membrane (49) although not yet determined in the human brain, and lipoamidase was found to be decreased by fucoidan in HepG2 cells. Lipoamidase has been known to catalyze the de-anchoring reaction for N-myristoylated and glycosyl-phosphatidyl-inositol (GPI)-bonded membrane-bound enzymes (50). Lipoamidase is also thought to be the recycling enzyme of lipoic acid (49, 50). Therefore, lipoamidase activity (47) and lipoic acid concentration (16) may be correlated. Then, the decrease of de-anchoring amidase (tissue-type lipoamidase) protein also seems to occur through changes in glycol-chains of the enzyme biotinidase. Although lipoamidase could hydrolyze the S-palmitoyl-anchored membrane proteins or not is as yet not established (50), S-palmitoylated viral proteins of genome polyprotein (*HCV*) and envelope glycoprotein gp160 (*HIV*) in HepG2 cells seem to be de-anchored (Table V). The ratio of cellular membrane proteins to the total cellular proteins was found to be increased from 29.0% to 43.2% by fucoidan treatment in HepG2 cells after three days (membrane proteins are indicated in Italics in (Tables VII-IX and X-XIII). Thus, the immediate increase of the ratio of membrane by fucoidan may be related to the direct inhibition of glycoprotein enzyme of de-anchoring enzyme lipoamidase by fucoidan *via* its glycochain. A similar direct inhibition of glycoprotein enzyme of biotinidase by Okinawa-fucoidan was recently reported by our group (6). The ratio of membrane proteins to the total cellular proteins is usually approximately 50% in normal liver biopsy specimens; *i.e.*, pseudo-liver cancer of 48.2%, LC tissue of leprosy 52.5%, LC tissue 36.0% and HCC tissue 26.5% of *HCV* infected patient, and HCC tissue of PBC patient 13.6%, respectively. Interestingly, Hc cells (immortal but non-cancer cell) from fetal tissue show that cellular membrane proteins are 23.9% of the total cellular proteins. This suggests that the ratio of membrane proteins seems directly linked to immortality (Tables II, III, IV). Since the ratio of membrane proteins to the total cellular proteins can be precisely, easily, and promptly determined within 3 h; *i.e.*, tissue homogenate is ultra-centrifugated at 100,000 $\times g$ for 1.5 h, and concentrations of proteins in the separated precipitated membrane- and soluble supernatant-fractions are determined by the fast SEC (3), thus, this ratio may become the most reliable diagnostic method for HCC and immortality. The incorporation of membrane proteins (or precursor membrane proteins) into the membrane structure requires for suitable metabolic conditions of glucose (51) and biotin concentration

(52). Thus, the amount or ratio of membrane may be depended on the lipoamidase protein and/or lipoamidase activity regulated by glycolchain, and on the metabolic state of the cells. Therefore, immortalized cell lines and HCC tissues may be in the condition of “de-anchored” or “state of the decreased membrane-protein”.

Fucoidan increases glycochain-synthesizing enzymes (from 2.2 to 4.9 $\mu g/mg$; 2.2-fold; Tables VII-IX and X-XIII in bold brown), although not yet conclusive since the database of genes of glycochain-synthesizing enzymes were uploaded only recently. However, this increase may be important for acquiring the normalized immunity through normalized glycolchains of the glycoproteins. Therefore, it is also interesting that fucoidan *per se* has the ability to perform innate immunity in the invertebrate shrimp (53). Since the reduction of +ssRNA virus, HCV and HIV are over 10-fold, the effect of fucoidan on the cellular protein synthesis linked to the differentiation (or gene expression) seems to be small or slow. Therefore, fucoidan may have a direct effect on glycol-chain synthesis and/or metabolism of the glycoproteins. Indirect therapies using glycol-chain compounds or immunological polysaccharides as antigens have already been performed on cancer patients in Japan; *i.e.*, glycochain antigen prepared from human-type tubercle bacilli SSM (Special Substance of Maruyama; *Maruyama vaccine*) (54) and glycol-lipid antigens prepared from the own or another patient’s urines (*Hasumi vaccine*) (55). Because fucoidan seems to have a direct effect on glycobiology and immunology together with the reduction of HIV and HCV on HepG2, the experiment for the therapy of chemically induced HCC by edible fucoidan from Silky-Mozuku in the rat has already been performed by us (56). It has been found that the successful therapy is observed only in the *SD* rat (outbred; constitutively possessing the normal immunity), but the tests with the *LEW* rat (inbred; without constitutively possessing the immunity genetically; generally used in the transplantation experiment) are all in vain (56).

In addition to the effects on proteins and glycoproteins, fucoidan from Japanese edible Ishi-Mozuku (*Sphaerotrichia divaricate*) at 0.102 mg/mL surely retarded the growth of HepG2 cells at 3 day’s treatment; collected and washed cell volume was decreased to 1/2 of the cell volume of untreated control, and two-fold lower volumes of homogenate were obtained, which was safely employed to comparative studies (Tables V to XIII). However, this fucoidan at 0.20 mg/mL did not retard the growth of normal Hc cells. On the other hand, it is noteworthy that fucoidan from Ireland’s non-edible Mozuku (*Fucus vesiculosus*) at 0.20 mg/mL killed and detached the Hc cells immediately within 3 days, and Hc cells could not be harvested using the cell scraper. With respect to apoptosis (or programmed cell death), apoptosis-related proteins (deoxyribonuclease, caspases, products of the genes p53, Livin, and XIAP) were not detected in HepG2

cells (both with and without fucoidan), in Hc cells, and liver tissues (both HCC and LC tissues) at all. However, by MTT assay measuring the mitochondrial-reducing ability of living cells with deteriorated cell membrane is widely employed for detecting apoptosis in biotechnological studies. The trypan blue method, by using another dye, is also used to measure dead cells with disrupted cell membranes. Therefore, the cellular-toxicity test (or apoptosis test) using lower concentrations of Ireland's non-edible Mozuku (*Fucus vesiculosus*) on Hc cells by the MTT assay may still be remained to be performed together with the direct volume-based growth test.

Analysis of gene expression is important for biological and clinical researches; *i.e.*, differentiation, development, ageing, cancer, and diseases researches. Analysis of messenger RNA (mRNA) instead of proteins is an indirect method, and it uses a hybridization technique with expensive DNA probes. Two-dimensional (2D) electrophoresis seems to be a direct protein analytical method, however electrophoresis of hydrophobic membrane proteins and the very-large MW proteins, such as titin, still remains a difficult issue (57). Therefore, sexual differentiation in response to mating hormone (S-farnesyl-dodecapeptide) has been previously studied by using only the soluble hydrophilic cellular proteins by our group, which indicated that unexpectedly small differences in the gene expression have occurred (8). On the other hand, this micro-sequencing method analyzes directly and generally both the membrane and soluble proteins expressed in the cells including viral and bacterial invaded-microbe proteins.

Thus, this micro-sequencing method is proven to be powerful tool for the identification and determination of the component proteins of biological specimens, which are useful in biosciences, such as clinical chemistry, diagnosis and therapy in medicine, biology, biochemistry, and biotechnology.

Conclusion

Approximately 250 proteins (including membrane proteins and invaded-microbe and viral proteins) are detected and determined in liver cell lines by the direct microsequencing-deciphering method.

This method is a direct and quantitative method; *i.e.*, this method is depended solely on the fidelity and preciseness of the automated-Edman reaction and determination of the PTH-amino acid with RP-HPLC.

It is found that edible fucoidan dramatically increases the ratio of membrane proteins and reduces +ssRNA viruses such as HCV and HIV in HepG2 hepatocarcinoma cells.

The mechanism of immortality based upon the glycobiology of HepG2 cells is presented herein. Furthermore, the prevention mechanism of this immortal growth of HepG2 by sulphated-polyfucose (fucoidan) has also been presented by the glycobiological and nutritional point of view.
